Enormous strains can exist in thin films when one material is deposited on another \((J)\), resulting from differences in crystal lattice parameters and thermal expansion behavior between the film and the underlying substrate or arising from defects formed during film deposition \((2, 3)\). As a result, the properties of thin films can be markedly different than the intrinsic properties of the corresponding unstrained bulk materials \((4–9)\). Although such strain often leads to degraded film properties, if judicious use is made of substrates and growth parameters, strain offers the opportunity to enhance particular properties of a chosen material in thin film form, namely strain engineering.

Strain engineering could facilitate the introduction of more environmentally benign ferroelectric random-access memories (FeRAM). Large shifts in the paraelectric-to-
ferroelectric transition temperature ($T_c$) and remanent polarization ($P_r$) are expected (10–14) and have been observed (15–17) in ferroelectrics, signaling the viability of a strain-engineered advance for FeRAM. The major disadvantages of the two materials most widely being pursued for FeRAM (18), PbZr,TiO$_3$ and SrBi$_2$Ta$_2$O$_9$, are (i) the volatility of the lead and bismuth constituents of these materials, which complicates their introduction into semiconductor fabrication facilities, and (ii) environmental issues associated with the toxicity of lead. We demonstrate that the ferroelectric properties of BaTiO$_3$ can be enhanced with the use of strain to make them viable for ferroelectric memory applications. The widespread use of (Ba,Sr)TiO$_3$ in semiconductor fabrication facilities for dynamic random-access memories (DRAM) greatly simplifies the introduction of this related material into silicon-based devices.

To predict the $T_c$ enhancement and the temperature dependence of the lattice parameters of BaTiO$_3$ thin films under large biaxial strains with the use of Landau thermodynamic theories (10), we determined a new set of phenomenological coefficients, because existing ones are only applicable to small compressive strains ($\leq$–0.4%) (11). Figure 1 shows the $T_c$ enhancement predicted from thermodynamic analysis for a BaTiO$_3$ thin film under biaxial strain $\varepsilon_a = (a_1^0 - a_0)/a_0$, where $a_0$ is the lattice parameter of free-standing cubic BaTiO$_3$ and $a_1$ is the in-plane lattice parameter of a biaxially strained (001) BaTiO$_3$ film. The green region shows the range in predicted $T_c$ resulting from the range of reported property coefficients for BaTiO$_3$ that enter into the thermodynamic analysis (19–21). Figure 1 implies that a bi-axial compressive strain of only $\sim$1% should be sufficient to produce strained (001) BaTiO$_3$ films with a $T_c$ comparable to or higher than unstrained PbZr,TiO$_3$ films.

Although Fig. 1 might seem to imply that $T_c$ can be enhanced without bound, there are limits to strain engineering. The driving force for film relaxation increases with strain and film thickness. When films are grown to thicknesses greatly exceeding their critical values, relaxation toward a zero-strain state by the introduction of dislocations begins. Thus, for strain engineering to be effective, it is important to grow films below, or at least close to, their critical thickness for relaxation. Because the critical thickness at which dislocations begin to form varies approximately inversely with lattice mismatch (1), lower mismatch is desired to allow the growth of strained BaTiO$_3$ films that are thick enough to allow their ferroelectric properties to be conveniently probed or used in devices. Notably, Fig. 1 only applies to thick strained ferroelectrics; as ferroelectrics get thin ($\sim$100 Å), their ferroelectric properties can be substantially diminished by finite-size effects (17, 22–24). Optimizing the trade-off between strain and film thickness depends on the particular application. For FeRAM, films several hundred angstroms in thickness are needed (25).

Table 1. Results from high-resolution x-ray diffraction measurements on the films. The in-plane $(a)$ and out-of-plane $(c)$ lattice constants and full width at half maximum (FWHM) of rocking curves of various peaks (002 of BaTiO$_3$ and SrRu$_2$O$_4$ on SrRuO$_2$ and 200$_{\text{cousine}}$ of GdScO$_3$ and DyScO$_3$) at room temperature are given. The $a$- and $c$-lattice parameters of single-crystalline BaTiO$_3$ are 3.992 and 4.036 Å, respectively (20).

To identify the ferroelectric phase transition, the temperature dependence of the in-plane and out-of-plane lattice parameters of films and substrates was measured with a variable-temperature four-circle x-ray diffractometer equipped with a two-dimensional (2D) area detector with an angular resolution of $\sim$0.02°. Unstrained BaTiO$_3$ undergoes a ferroelectric transition at about 130°C from the high-temperature cubic phase (Pn3m) to the low-temperature tetragonal phase (P4mm) (20). Figure 2A shows 2D images of the 002 and 202 diffraction peaks at selected temperatures from a BaTiO$_3$ single crystal as well as from coherent BaTiO$_3$ thin films grown on (110) GdScO$_3$ and (110) DyScO$_3$ substrates. There is no substantial change in the diffraction peaks of the BaTiO$_3$ thin films that are at or above $T_c \sim 130°C$. As expected, the single diffraction spot of the BaTiO$_3$ single crystal splits into two below 130°C, corresponding to $a$ and $c$ domains of the tetragonal (P4mm) ferroelectric phase.

The in-plane and out-of-plane lattice parameters of the strained BaTiO$_3$ films grown by MBE were determined from the 002 and 202 diffraction peaks and are plotted as a function of temperature in Fig. 2B. The in-plane lattice parameters of the BaTiO$_3$ are coherent to the underlying substrates over the entire temperature range (25° to 700°C). There are marked differences in the evolution of the lattice parameters with temperature between the unstrained BaTiO$_3$ single crystal and the strained BaTiO$_3$ thin films. Notably, the BaTiO$_3$ thin films never become cubic; they remain tetragonal as a result of the strain. The green region represents the range (error bars) in the predicted $T_c$ resulting from the spread in reported property coefficients (20, 21) for BaTiO$_3$ that enter into the thermodynamic analysis. The data points show the observed $T_c$ and $P_r$ values of coherent BaTiO$_3$ films grown by MBE on GdScO$_3$ (blue circle) and DyScO$_3$ (red circle) substrates and by PLD on GdScO$_3$ (blue square) and DyScO$_3$ (red square) substrates.
sult of the biaxial substrate constraint. The predicted dependence of the c-lattice parameter of biaxially strained BaTiO$_3$ with and without a ferroelectric phase transition, was calculated from thermodynamic analysis (10) and is shown by the green solid and dashed curves in Fig. 2B, respectively. Because the BaTiO$_3$ film is clamped in-plane, all structural changes resulting from the phase transition and thermal expansion are accommodated through changes in the out-of-plane lattice parameter only. The agreement between the solid line prediction and the measured c-axis lattice parameters in Fig. 2B is strong evidence that the change in slope in the c-axis lattice parameter at high temperature corresponds to a ferroelectric phase transition. Analogous lattice constant behavior has been observed in other constrained ferroelectric films (15, 17), is consistent with theory (13, 17), and has been used to determine $T_c$. The $T_c$ of the coherent BaTiO$_3$ thin films shown in Fig. 2B is ~400°C on GdScO$_3$ and ~540°C on DyScO$_3$.

To confirm the huge shifts in $T_c$, we attempted to measure polarization hysteresis loops on a 2000-A-thick coherent BaTiO$_3$ film grown by PLD on a coherent SrRuO$_3$ bottom electrode on (110) GdScO$_3$. At temperatures up to about 200°C, hysteresis loops were clearly seen, but at higher temperatures the dielectric losses in the films became too high for reliable measurements. We made second harmonic generation (SHG) measurements as a function of temperature on this PLD-grown BaTiO$_3$/SrRuO$_3$/GdScO$_3$ sample as well as the MBE-grown BaTiO$_3$/GdScO$_3$ sample, whose lattice constants versus temperature behavior is shown in Fig. 2B (21). An SHG signal is only exhibited by materials that lack inversion symmetry. All ferroelectrics must lack inversion symmetry, but there are many materials that lack inversion symmetry and are not ferroelectric. This makes SHG a necessary but insufficient probe for ferroelectricity. Nonetheless, SHG (Fig. 2C) shows that the phase we know from hysteresis loops to be ferroelectric at room temperature remains noncentrosymmetric to the same high temperature (29, 30) at which x-ray diffraction indicates a phase transition. The interpretation consistent with all our analyses—x-ray diffraction, SHG, and hysteresis measurements—is that biaxial compressive strain increases the $T_c$ of BaTiO$_3$.

Hysteresis measurements were made on 200-μm-diameter capacitors of strained BaTiO$_3$ thin films sandwiched between epitaxial top and bottom electrodes of the conducting perovskite oxide SrRuO$_3$ (31). High-resolution x-ray diffraction measurements (summarized in Table 1) revealed the BaTiO$_3$ ferroelectric layers as well as the MBE-grown BaTiO$_3$/SrRuO$_3$/GdScO$_3$ stack was grown with a 2000-A-thick BaTiO$_3$ layer on DyScO$_3$ and was too high for good ferroelectric hysteresis measurements, a SrRuO$_3$/BaTiO$_3$/SrRuO$_3$/DyScO$_3$ stack was grown on a 2000-A-thick BaTiO$_3$ layer. This latter stack had low leakage; however, it was partially relaxed.

Figure 3A shows the ferroelectric hysteresis loops measured on the ferroelectric stacks grown on GdScO$_3$ and DyScO$_3$ substrates with 2000-A-thick BaTiO$_3$ layers, together with results from a BaTiO$_3$ single crystal (32). The hysteresis loops are shifted in the positive voltage direction. This imprint effect is probably due to the asymmetric interfacial properties of the top and bottom electrodes to the BaTiO$_3$ films. Even though we used SrRuO$_3$ for both electrodes, the growth temperature (350°C) of the top electrode was much lower than that of the bottom electrode (680°C), which might lead to poor crystallinity of the top electrode and
asymmetric interfaces. The $P_s$ and coercive field ($E_c$) were determined to be $\sim 50 \mu C/cm^2$ and 80 kV/cm for the fully coherent BaTiO$_3$/GdScO$_3$ sample and $\sim 70 \mu C/cm^2$ and 25 kV/cm for the partially relaxed BaTiO$_3$/DyScO$_3$ sample, respectively. This $P_s$ value is almost 270% of the 26 $\mu C/cm^2$ assumed in the scaling analysis of FeRAM (18), and comparable to the $P_s$ of unstrained Pb(Zr,Ti)O$_3$ films (33). As this $P_s$ of $\sim 70 \mu C/cm^2$ was observed in a partially relaxed sample with $\varepsilon_{33}$ of $-1.3\%$, a coherently strained BaTiO$_3$/DyScO$_3$ sample with $\varepsilon_{33}$ of $-1.7\%$ could have an even higher $P_s$.

Another important issue for the application of ferroelectric capacitors to memory devices is the loss of switched polarization after repeated switching, i.e., fatigue. We performed fatigue measurements by applying 8.6-$\mu$s-wide pulses with a repetition frequency of 10 kHz to the top and bottom SrRuO$_3$ electrodes of the SrRuO$_3$/BaTiO$_3$/SrRuO$_3$/GdScO$_3$ structure at $V_{max} = 4 \, V$, where $V_{max}$ is the amplitude of the voltage pulse. $V_{max} = 4 \, V$ corresponds to 200 kV/cm of the electric field. The switched polarization decreased by 10% of its original value after 10$^6$ fatigue cycles, but recovered its original value after 10$^{10}$ cycles. This is consistent with previous observations of fatigue-free behavior when conducting oxide electrodes are used (34, 35).

As a check that the enhancement of $T_c$ observed in coherently strained BaTiO$_3$ thin films grown by MBE (Fig. 2B) is inherent and applicable to a device structure with a conductive bottom electrode, we performed high-temperature x-ray diffraction measurements on the coherent BaTiO$_3$ thin films with SrRuO$_3$ bottom electrodes grown by PLD. Figure 3B shows the evolution of the in-plane (a) and out-of-plane (c) lattice parameters of the BaTiO$_3$ film and the GdScO$_3$ and DyScO$_3$ substrates as a function of temperature. The in-plane lattice parameters reveal that both the BaTiO$_3$ and SrRuO$_3$ layers are coherently strained to the underlying substrates over the entire temperature range. This is consistent with the absence of misfit dislocations along the interface between GdScO$_3$ and SrRuO$_3$ and along the interface between SrRuO$_3$ and BaTiO$_3$, as shown by the cross-sectional transmission electron microscope images in Figs. S1 and S2 (21). As seen in the figure, the transition behavior of the PLD samples is quite similar to those grown by MBE. $T_c$ was determined to be $\sim 420^\circ$C and $\sim 680^\circ$C for samples grown on GdScO$_3$ and DyScO$_3$, respectively. The green solid and dashed lines in Fig. 3B are theoretical predictions of c-lattice parameters with and without the ferroelectric phase transition, which are fairly consistent with the experimentally measured values. The agreement in the results for films grown by MBE and PLD indicates that the observed shifts in ferroelectric properties with strain represent the intrinsic behavior of strained BaTiO$_3$. This experimental dependence of $T_c$ on $\varepsilon_{33}$ is also consistent with the expectations shown in Fig. 1.

In summary, we have demonstrated that the ferroelectric properties of BaTiO$_3$ can be markedly enhanced through strain engineering. These strain-engineered heteroepitaxial thin films provide a broad range of operating temperatures as well as higher remanent polarization for improved noise immunity and the ability to scale FeRAM to smaller cell sizes. Another application of strain-engineered BaTiO$_3$ films is high-speed electro-optic modulators, in which the sizeable electro-optic coefficients of BaTiO$_3$ can be enhanced by appropriate strain engineering. The ability to withstand huge strains gives thin films a degree of freedom absent from bulk. This can be exploited to enhance the ferroelectric properties of any ferroic system, including multiferroics (8, 22, 36), whose ferroic order parameter has a strong coupling to strain.

Fig. 3. (A) Polarization-electric field hysteresis loops of BaTiO$_3$ thin film capacitors (2000 Å) grown by PLD on GdScO$_3$ and DyScO$_3$ with SrRuO$_3$ top and bottom electrodes. The inset shows the hysteresis loop of an unstrained bulk BaTiO$_3$ single crystal for comparison (32). (B) Temperature dependence of the lattice parameters of strained SrRuO$_3$/BaTiO$_3$/SrRuO$_3$ capacitor structures grown by PLD on DyScO$_3$ substrates and GdScO$_3$ substrates. The in-plane (f) and out-of-plane (l) lattice constants of the BaTiO$_3$ thin films, SrRuO$_3$ bottom electrode, and underlying substrates are shown. The lattice parameters of the SrRuO$_3$ film on DyScO$_3$ could not be resolved because SrRuO$_3$ and DyScO$_3$ are isostructural with very similar lattice parameters. The change in slope at high temperature indicates a phase transition. The error bars (±SD) of the measured lattice constants are shown to the left of each curve. The measured values of the out-of-plane lattice constant of biaxially strained BaTiO$_3$ are compared with theoretical predictions (10, 27) with and without a ferroelectric transition.
Cation Exchange Reactions in Ionic Nanocrystals

Dong Hee Son, Steven M. Hughes, Yadong Yin, A. Paul Alivisatos

Cation exchange has been investigated in a wide range of nanocrystals of varying composition, size, and shape. Complete and fully reversible exchange occurs, and the rates of the reactions are much faster than in bulk cation exchange processes. A critical size has been identified below which the shapes of complex nanocrystals evolve toward the equilibrium shape with lowest energy during the exchange reaction. Above the critical size, the anion sublattice remains intact and the basic shapes of the initial nanocrystals are retained throughout the cation exchange. The size-dependent shape change can also be used to infer features of the microscopic mechanism.

Chemical transformations from one solid to another via insertion and exchange of atoms can be used to modify the properties of crystalline materials (1). Recent developments have enabled the production of many technologically important crystalline materials in nanometer sizes, with a wide range of size- and shape-tunable properties (2–8). Of particular interest is the creation of nanocrystals with nonequilibrium shapes and with higher structural and compositional complexity (9–13). In extended solids, reactions involving chemical transformation are in general very slow because of high activation energies for the diffusion of atoms and ions in the solid. For this reason, typical solid-phase reactions require very high temperatures or pressures (14–16) and therefore would seem to be incompatible with kinetically controlled nonequilibrium nanostructures.

However, in crystals only a few nanometers in size, both the thermodynamics and kinetics of reactions can change with size. For example, a large surface-to-volume ratio can be accompanied by a lowering of phase transition temperatures (17, 18). With the decrease in the volume, statistical averaging of the kinetics and mechanisms over a distribution of heterogeneous reaction sites intrinsic to the bulk solid is also reduced, leading to more homogeneous molecule-like reaction kinetics and even different reaction mechanisms in nanocrystals (19). The optimal use of various chemical transformation methods to broaden the range of nanocrystalline materials depends on an understanding of how chemical transformations in a crystalline solid will be affected by a reduction in size. We show that cation exchange reactions can occur completely and reversibly in ionic nanocrystals at room temperature with unusually fast reaction rates. We also show that the crystal structure and morphology of the reaction products are strongly dependent on the size and shape of the nanocrystals.

The prototypical semiconductor nanocrystal system of CdSe reacts with Ag
to yield Ag2Se nanocrystals by the forward cation exchange reaction, and vice versa for the reverse cation exchange reaction. We chose to work with CdSe nanocrystals because of the high degree of control over size and shape that has been achieved (2, 3). The conversion to Ag2Se is strongly favored by a thermodynamic driving force of about ~1000 kJ/mol in the bulk (20, 21). Ag2Se also exhibits an interesting temperature-dependent polymorphism: The superionic conducting phase transition occurs at a relatively low temperature of 133°C in the bulk phase (22). Thus, it may be possible to prepare Ag2Se with unusually high cation mobility. These two factors favor complete cation exchange in nanocrystals and may prove sufficient to overcome the fact that the exchange reaction is completely kinetically hindered at ambient temperature and pressure in the bulk.

We investigated the reaction by mixing a solution of CdSe nanocrystals (diameter 4.2 nm) in toluene with a small amount of methanolic solution of AgNO3 under ambient conditions. The volume fraction of methanol in the solution mixture is about 1%; the solution contains Ag+ ion in a slightly larger amount than necessary to replace all the Cd2+ ions in the nanocrystals. Methanol more strongly binds to any free binary cations in solution and thus favors the forward reaction. A rapid (<1 s) change of solution color and complete disappearance of fluorescence is observed upon mixing the solutions. Measurements of the x-ray diffraction (XRD) patterns and optical absorption spectra confirm that the reaction product is Ag2Se (Fig. 1). The reverse reaction is done under ambient conditions by mixing Ag2Se nanocrystals with an excess amount (typically 50 to 100 times the initial Cd2+ content) of Cd(NO3)2 in a mixture of toluene and methanol in the presence of tributylphosphine (volume fraction <3%). A slower color change back to that of CdSe nanocrystals and the reappearance of fluorescence are observed over a period of 1 min. XRD patterns, optical absorption, and fluorescence spectra all indicate that CdSe is recovered from the reverse cation exchange. The XRD linewidths of the initial and recovered case are nearly identical. Moreover, the absorption and fluorescence peak positions, which show strong size dependence due to the quantum confinement effect (2), are also nearly identical for the initial and recovered CdSe nanocrystals. Finally, transmission electron microscopy (TEM) images of the initial and recovered
**Thermodynamic Calculations**

In a phenomenological description of the ferroelectric phase transitions in BaTiO$_3$, the spontaneous polarization $\mathbf{P} = (P_1, P_2, P_3)$ is chosen as the order parameter. The Landau-Devonshire free energy, $f$, is usually expanded as a polynomial of the polarization components $P_i$ ($i = 1, 2, 3$). The order of the polynomial should be at least fourth-order for a second-order transition and sixth-order for a first-order transition ($I$, $2$). In order to describe the three ferroelectric transitions in a BaTiO$_3$ single crystal, i.e., from paraelectric cubic to ferroelectric tetragonal, orthorhombic and rhombohedral, we expressed the Landau-Devonshire free energy with an eighth-order polynomial. Under stress-free conditions it is

$$f = \alpha_1 \left( P_1^2 + P_2^2 + P_3^2 \right) + \alpha_{11} \left( P_1^4 + P_2^4 + P_3^4 \right) + \alpha_{12} \left( P_1^2 P_2^2 + P_2^2 P_3^2 + P_1^2 P_3^2 \right) + \alpha_{111} \left( P_1^6 + P_2^6 + P_3^6 \right) + \alpha_{112} \left[ P_1^2 \left( P_2^4 + P_3^4 \right) + P_2^2 \left( P_1^4 + P_3^4 \right) + P_3^2 \left( P_1^4 + P_2^4 \right) \right] + \alpha_{1111} \left( P_1^8 + P_2^8 + P_3^8 \right) + \alpha_{1112} \left[ P_1^4 \left( P_2^6 + P_3^6 \right) + P_2^4 \left( P_1^6 + P_3^6 \right) + P_3^4 \left( P_1^6 + P_2^6 \right) \right] + \alpha_{1122} \left( P_1^4 P_2^4 + P_2^4 P_3^4 + P_1^4 P_3^4 \right) + \alpha_{1113} \left( P_1^2 P_2^2 P_3^2 + P_2^2 P_3^2 P_1^2 + P_3^2 P_1^2 P_2^2 \right),$$

where all of the coefficients are assumed to be temperature-independent except

$$\alpha_i = (T - \theta)/(2\varepsilon_0 C) = \alpha_0 (T - \theta),$$

$\varepsilon_0$ is the permittivity of vacuum, $C$ is the Curie-Weiss constant, and $\theta$ is the Curie-Weiss temperature.

The free energy of a tetragonal $c$-domain with $\mathbf{P} = (0, 0, P_3)$ in a BaTiO$_3$ film as a function of biaxial compressive strain, $\varepsilon_x$, is given by

$$f_{T}^{\text{film}} = \left( \alpha_1 + \beta_3 \right) P_3^2 + \left( \alpha_{11} + \beta_{33} \right) P_3^4 + \alpha_{111} P_3^6 + \alpha_{1111} P_3^8 + \frac{\varepsilon_x^2}{s_{11} + s_{12}},$$

(2)
with $\beta_3 = -\frac{2Q_{12} \varepsilon_s}{s_{11} + s_{12}}$ and $\beta_{33} = -\frac{Q_{12}^2}{s_{11} + s_{12}}$, where $Q_{11}$ and $Q_{12}$ are the electrostrictive coefficients and $s_{11}$ and $s_{12}$ are elastic compliances. The spontaneous polarization of a tetragonal $c$-domain as a function of temperature can be obtained by minimizing the free energy, Eq. (2), with respect to $P_3$.

When the transition from paraelectric to tetragonal is second-order, the transition temperature can be obtained through $\alpha_1 + \beta_3 = 0$, i.e.,

$$T_c = \theta + 2\varepsilon_0 C \frac{2Q_{12}}{s_{11} + s_{12}} \varepsilon_s,$$

If the transition is first-order, the transition temperature will be larger than that given by Eq. (3), but the difference will be less than 10 °C, since it is a weak first-order transition (I). The calculated transition temperature of the films as a function of strain (Fig. 1) has a range due to the discrepancy among the reported data for the relevant coefficients for single crystal BaTiO$_3$ (I, 4-7), i.e., $Q_{11} = (0.100$ to $0.113$) m$^4$/C$^2$, $Q_{12} = (-0.050$ to $-0.034$) m$^4$/C$^2$,

$C = (1.37$ to $1.73) \times 10^5$ °C, $s_{11} + s_{12} = (5.2$ to $6.4) \times 10^{-12}$ m$^2$/N, and $\theta = (110$ to $118)$ °C.

By taking into account the stress-free surface condition and the biaxial substrate constraint, the out-of-plane lattice parameter, $c$, as a function of temperature can be calculated from

$$c = a_c \left[ 1 + \left[ \frac{2s_{12} \varepsilon_s}{s_{11} + s_{12}} + P_3^2 \left( Q_{11} - \frac{2s_{12} Q_{12}}{s_{11} + s_{12}} \right) \right] \right],$$

where $a_c$ is the lattice constant of stress-free bulk cubic BaTiO$_3$. In calculating $c$ from Eq. (4) for Figs. 2B and 3B, specific values of the relevant coefficients are used so the shape of the curve is not obscured by the range of coefficient values. The following coefficients are used:

$Q_{11} = 0.10$ m$^4$/C$^2$, $Q_{12} = -0.034$ m$^4$/C$^2$ (4); $s_{11} = 9.1 \times 10^{-12}$ m$^2$/N, $s_{12} = -3.2 \times 10^{-12}$ m$^2$/N (7, 8);
$C_0 = 1.37 \times 10^5$ (from the dielectric constant measurements we made on the same BaTiO$_3$ single crystal whose lattice parameters as a function of temperature are shown in Fig. 2A); $\theta = 115^\circ C$ (9); $\alpha_{i1} = -508.55 \alpha_0 \text{ N m}^6/\text{C}^4$, $\alpha_{i11} = 3137.11 \alpha_0 \text{ N m}^{10}/\text{C}^6$; $\alpha_{i111} = 93673.45 \alpha_0 \text{ N m}^{14}/\text{C}^8$.

These values are from our new fitting of the data for BaTiO$_3$ single crystals under stress-free conditions, yielding $P_c = 18.12 \mu \text{C/cm}^2$ at the transition temperature $T_c = 125^\circ C$, $P_s = 26 \mu \text{C/cm}^2$ at $T = 25^\circ C$ and $P_s = 23 \mu \text{C/cm}^2$ at $T = 87^\circ C$. The details of the determination of these coefficients will be reported in a follow-up paper (10). Considering the experimental results in Figs. 1, 2B, and 3B, these coefficients seem to be well suited to the BaTiO$_3$ films grown by both MBE and PLD in this study.

**Substrates**

The (110) GdScO$_3$ and (110) DyScO$_3$ substrates used are two of a series of rare-earth scandates with pseudocubic lattice constants that range from 3.93 Å to 4.05 Å in roughly 0.01 Å increments as the rare earth species is varied (11-17). These rare earth scandates have the GdFeO$_3$-type orthorhombic structure (space group: $Pbnm$). GdScO$_3$ has lattice constants $a = 5.488 \text{ Å}$, $b = 5.746 \text{ Å}$, and $c = 7.934 \text{ Å}$ (14) and DyScO$_3$ has lattice constants $a = 5.440 \text{ Å}$, $b = 5.713 \text{ Å}$, and $c = 7.887 \text{ Å}$ (15). In these structures the (110) plane, spanned by [1 1 0] and [001] directions, provides a nearly square base with $c/2 = 3.967 \text{ Å}$ and $\sqrt{a^2 + b^2}/2 = 3.973 \text{ Å}$ for the in-plane surface mesh of (110) GdScO$_3$ (14, 17) and $c/2 = 3.943 \text{ Å}$ and $\sqrt{a^2 + b^2}/2 = 3.944 \text{ Å}$ for (110) DyScO$_3$ (15, 17). Thus, (110) GdScO$_3$ and (110) DyScO$_3$ substrates provide $\varepsilon_s$ of about $-1.0\%$ and $-1.7\%$, respectively, for the epitaxial growth of coherent (001) BaTiO$_3$ films.
**Thin Film Growth**

Epitaxial BaTiO$_3$ thin films were grown on (110) GdScO$_3$ and (110) DyScO$_3$ substrates by both MBE and PLD. For the films grown by MBE, molecular beams of the constituent elements were supplied to the surface of untwinned (110) GdScO$_3$ and (110) DyScO$_3$ substrates held at 700 °C. A mixture of 90% O$_2$ and 10% ozone at a background pressure of 5×10$^{-6}$ Torr was used as the oxidant, incident upon the substrate via a directed inlet nozzle. The BaTiO$_3$ was deposited by the sequential deposition of BaO and TiO$_2$ monolayers, where each monolayer dose was controlled in real time by feedback from reflection high-energy electron diffraction (RHEED) intensity oscillations (18). To grow BaTiO$_3$ films by PLD, untwined (110) GdScO$_3$ and (110) DyScO$_3$ substrates were attached to a resistive heater and positioned 5.0 cm from the target. A KrF excimer laser (248 nm) beam was focused on a stoichiometric BaTiO$_3$ target to an energy density of 2.0 J/cm$^2$ and pulsed at 5 Hz. BaTiO$_3$ films were grown at substrate temperatures ranging from 650 to 800 °C and oxygen pressures of 100-150 mTorr. The PLD system is equipped with high-pressure RHEED, which enabled the layer-by-layer growth of the thin films to be monitored in situ during growth.

**Structural Characterization**

The three-dimensional strain state of the films was determined using high-resolution four-circle x-ray diffraction. The crystalline perfection of the films was assessed by measuring the full width at half maximum (FWHM) in $\omega$ (rocking curve) of the 002 BaTiO$_3$ reflection.

The microstructure and interfacial structure of the BaTiO$_3$ thin films grown on both GdScO$_3$ and DyScO$_3$ substrates were characterized by cross-sectional transmission electron microscopy (TEM). Figure S1A is a bright-field TEM image showing a 200 nm thick BaTiO$_3$ film grown on a (110) GdScO$_3$ substrate with a (110) SrRuO$_3$ bottom electrode layer. The
corresponding selected area electron diffraction patterns for each film layer and the substrate are also shown in Fig. S1. It was found that the BaTiO$_3$ film grows epitaxially and is purely $c$-axis oriented normal to the substrate through the whole film. No misfit dislocations are seen along the interface between GdScO$_3$ and SrRuO$_3$ or along the interface between SrRuO$_3$ and BaTiO$_3$. This indicates that both the SrRuO$_3$ and BaTiO$_3$ films are strained to the lattice spacing of the substrate by coherent epitaxial growth, which is consistent with the x-ray data shown in Fig. 3B and Table 1. The change in the diffraction contrast of the BaTiO$_3$ film indicates that the film is highly strained. High-resolution TEM images of the BaTiO$_3$/SrRuO$_3$ and SrRuO$_3$/GdScO$_3$ interfaces are shown in Fig. S2. Sharp interfaces are seen both between GdScO$_3$ and SrRuO$_3$ and between SrRuO$_3$ and BaTiO$_3$. The position of the interfaces is indicated by dashed lines.

**Fig. S1.** (A) Bright-field TEM image showing a 200 nm thick BaTiO$_3$ film grown on a (110) GdScO$_3$ substrate with a (110) SrRuO$_3$ bottom electrode layer. (B), (C), and (D) Selected area electron diffraction patterns corresponding to the BaTiO$_3$ and SrRuO$_3$ films and the GdScO$_3$ substrate, respectively.

**Second Harmonic Generation Measurements**

A schematic of the SHG measurement is shown in Fig. S3.
Fig. S3. A schematic of the geometry of the SHG measurement (not to scale). The wavevectors $k_\omega$ and $k_{2\omega}$, for fundamental frequency ($\omega$) and second harmonic frequency (2$\omega$), are shown. The incidence and refraction angles $\varphi$, are also shown, with subscripts, $i$, $s$, $f$, and $t$, corresponding to incidence, substrate, film, and transmitted, respectively.

To measure the polar plots in the inset of Fig. 2C, incident light at frequency $\omega$ (wavelength 900 nm) was polarized at an angle of $\theta$ to the $x$-$y$ plane and $\varphi_i = 23^\circ$ to the surface normal ($z$) of the GdScO$_3$ substrate. The incident fundamental polarization was $p$-polarized and the output SHG polarization ($I_{2\omega}$ at frequency 2$\omega$ (wavelength of 450 nm)) was $p$-polarized ($\theta = 0^\circ$) for the film and $s$-polarized ($\theta = 90^\circ$) for the single crystal.

The general expression for this SHG intensity is given by (19-21)

$$I_{2\omega} = K_1 \left( \cos^2 \theta + K_2 \sin^2 \theta \right)^2 + K_3 \sin^2 (2\theta),$$

where $K_1$, $K_2$, and $K_3$ are constants that depend on nonlinear coefficients ($d_{31}$, $d_{33}$, and $d_{15}$), geometric factors involving Fresnel coefficients, angles shown in Fig. S3, and microstructural parameters involving the relative area fraction of various polarization variants (domains) in the BaTiO$_3$ film. Detailed analysis of the derivation, and the physical significance of all the fitting parameters will be reported elsewhere.
No SHG signal was detected for normal incidence on the film system ($q_3 = 0^\circ$) in Fig. 2C, confirming that the strained BaTiO$_3$ film is indeed predominantly $c$-axis (001) oriented. X-ray diffraction measurements revealed that following the temperature cycling of the SHG measurement shown in Fig. 2C, the film contained ~0.8% by volume of $a$-domains. These domains have polarization $P_s$ along the $\pm x$ and $\pm y$ directions.

The first term in Eq. (5) involving the constants $K_1$ and $K_2$ arises predominantly from domains with polarization $P_s$ along the $\pm z$ directions, and possibly a small amount of contribution from domains with $P_s$ along the $\pm x$ directions. The second term arises from a small SHG contribution from domains with polarization $P_s$ along the $\pm y$ directions. The ratio, $F^o(\theta = 0^\circ)/F^o(\theta = 90^\circ) = 1/K_2^2$, corresponding to the ratio of $p$-to-$s$ polarized SHG intensity from the film, is related purely to intrinsic nonlinear coefficients of the film ($d_{31}$, $d_{33}$, and $d_{15}$) and fixed geometric factors, and is independent of the film domain microstructure. Numerical fitting of the polar plots yields the constant $1/K_2 = -2.2 \pm 0.01$, which is therefore related to intrinsic BaTiO$_3$ material properties. This constant is found to remain constant between 50 °C and 400 °C in the polar plots, but decreases thereafter in polar plot measurements up to 700 °C. This indicates a discontinuity in the intrinsic material property beyond the $T_c$ in the strained BaTiO$_3$ film.
